We present a microscopic calculation of the energy dissipation in the core of a vortex moving in a two-dimensional or layered superconductor in the moderately clean regime. In this regime, the quasiclassical Bardeen-Stephen result remains valid in spite of the strong correlations between the energy levels. We find that the quasiclassical expression applies both in the limit of fast vortex motion (with transitions between smeared levels) and in the limit of slow vortex motion (with nearly adiabatic dynamics). This finding can be related to the similar result known for the unitary random-matrix model.

I. INTRODUCTION

At low temperature, the energy dissipation in vortex cores is the main source of resistivity in the mixed state of type-II superconductors.1 If a supercurrent flows through a superconductor, it exerts a force on the vortices. Unless pinned by impurities or inhomogeneities, the vortices are brought into motion, which in turn leads to dissipation. Depending on the level of disorder, the vortices may move at different angles with respect to the direction of the supercurrent. At weak disorder, the vortices move together with the supercurrent (“ballistic limit,” with the Hall angle close to π/2). At sufficiently strong disorder, the vortex motion is directed perpendicular to the supercurrent (“dissipative limit,” small Hall angle). Both limits are well understood within the quasiclassical description.2–7 A simplified approach describing the dissipative limit goes back to the theory of Bardeen and Stephen treating the vortex as a region of normal phase in a two-dimensional or layered superconductor.6–8 In spite of neglecting the structure of the quasiparticle excitations in the vortex core,9 the Bardeen-Stephen theory gives the same result (up to a numerical factor) as the accurate quasiclassical calculation.2–7

It has been recently suggested that the microscopic structure of the core excitations may play a much more prominent role in that part of the dissipative regime where the excitation spectrum remains discrete (sharp quasiparticle levels), specifically in layered superconductors.10–13 In the clean limit (i.e., for scattering rates h/τ much smaller than the superconducting gap Δ), the motion of quasiparticles in the vortex core is ballistic: they cross the vortex core many times before scattering off impurities. Therefore in this limit, the spectral properties are sensitive to the details of disorder realization. In the superclean regime (h/τ ≪ Δ/EF, where EF is the Fermi energy), the levels inside a two-dimensional vortex split into two sets (“combs”) of equally spaced levels.11 The transformation of this correlated spectrum into a featureless uncorrelated one with increasing disorder proceeds in distinct steps: within the moderately clean regime (Δ2/EF ≪ h/τ ≪ Δ), a new intermediate region (Δ2/EF ≪ h/τ ≪ Δ/EF) has been found,11,12 where the comb structure remains preserved but is randomly shifted in energy (the number of impurities in the core has to be small enough to preserve the combs, while being large enough to randomize the overall shift). Increasing the impurity concentration further (already in the moderately clean limit for weak impurities,14 and ultimately in the dirty limit15), the comb structure is destroyed with a crossover to the class C random-matrix ensemble.16

Keeping within the moderately clean regime with a discrete spectrum, in two-dimensional (or layered) superconductors there further exist two limits of dissipation:10 The first one applies to the slowly moving vortex with a discrete quasiparticle spectrum (“discrete-spectrum regime”), where the dissipation is due to Landau-Zener transitions between individual levels.17,18 The second limit is with levels smeared into a continuum either by the vortex motion or by inelastic processes (“continuum-spectrum regime”); the dissipation then is given by the linear-response Kubo formula.19 At low temperatures, the inelastic smearing can be neglected and the crossover between these two regimes is controlled by the vortex velocity with the characteristic velocity given by vK ∼ (Δ/EF)/√kF l (here, Δ is the superconducting gap and l denotes the elastic mean free path10).

In the framework of random-matrix models with time-dependent Hamiltonians, the dissipation in the discrete-spectrum and continuum-spectrum regimes was considered by Wilkinson.18 He finds that, in the case of the unitary Wigner-Dyson ensemble, the linear dissipative response remains valid in the whole range of velocities, both in the continuum-spectrum (high-velocity) and in the discrete-spectrum (low-velocity) regimes. Based on this fact and on the similarity between the unitary and class C ensembles, it was shown that with the class C level statistics the dissipation rate nearly follows the Bardeen-Stephen prediction, even in the limit of small velocities v < vK where the quasiclassical description is no longer valid.10 Contrary, it was claimed in Ref. 12 that the additional correlation between levels (the “two-comb” structure) may lead to an anomalously high vortex viscosity in the moderately clean regime in the low-velocity limit.

In our paper, we reconsider the problem of the vortex viscosity in a two-dimensional s-wave superconductor, taking full account of the discreteness of the vortex spectrum and of the microscopic structure of the quasiparticle levels. We assume the moderately clean limit with an appropriate number of impurities in the core, such that the spectrum...
possesses the randomly shifted two-comb structure (the precise condition is given in Sec. III). We find that in spite of the level correlations derived in Refs. 11 and 12, the vortex viscosity does not differ from the well-known quasiclassical result\textsuperscript{7,21} for three-dimensional superconductors. Within the same microscopic model we consider separately the discrete-spectrum and continuum-spectrum regimes of dissipation: in both limits we arrive at the Bardeen-Stephen result for the dissipation,
\[
\sigma_{xx} = \frac{e^2 c n \omega_0 \tau}{B} \sim \frac{\hbar c}{n B},
\]
where \(n\) is the electron density, \(\hbar = h/2\pi\) and \(B\) is the magnetic field. The two-comb level structure found in Refs. 11 and 12 may be classified as the circular unitary random-matrix ensemble. We also find the scattering time \(\tau\) for quasiparticles in the core,\textsuperscript{7} and \(B\) is the magnetic field. Therefore, our findings may be considered as a generalization of Wilkinson’s results\textsuperscript{15} to circular ensembles.

The paper is organized as follows. In Sec. II, we prepare for the calculation by deriving the microscopic Hamiltonian projected onto the relevant subgap states in the vortex core. In Sec. III we review the results of Refs. 11 and 12 on the circular random-matrix ensemble appearing in a disordered vortex at the intermediate level disorder. We then describe the two limiting regimes of dissipation (Sec. IV), the discrete-spectrum and the continuum-spectrum regimes, and set up the stage for the calculations. In Sec. V, we treat the case of the discrete energy spectrum (low velocities and no inelastic level broadening), while Sec. VI is devoted to the opposite continuum-spectrum limit where the levels are broader than the interlevel distance. Finally, we discuss our findings in Sec. VII. The sensitivity of the energy levels to the vortex disorder is calculated in the Appendix.

**II. MICROSCOPIC HAMILTONIAN OF THE MOVING VORTEX**

Before discussing the moving vortex, let us review the excitation spectrum of a clean two-dimensional vortex at rest. The corresponding wave functions are given by the solutions to the Bogoliubov–de Gennes equations
\[
\begin{pmatrix}
H_0 & \Delta(r) \\
\Delta^*(r) & -H_0
\end{pmatrix}
\begin{pmatrix}
u \\
u^*
\end{pmatrix} = E
\begin{pmatrix}
u \\
u^*
\end{pmatrix},
\]
where \(H_0 = \frac{\hbar^2}{2m} \vec{r}^2 - E_F\). We assume an axially symmetric vortex with the order parameter \(\Delta(r) = \Delta(r)e^{i\theta}\), where the modulus of the order parameter depends only on the radial component \(r\) and the phase winds with the angular coordinate \(\theta\). We neglect the magnetic field in the vortex core, assuming a large magnetic penetration depth \(\lambda \gg \xi\), where \(\xi = v_F/\pi \Delta\) is the superconducting coherence length (here and below we choose units with \(\hbar = 1\)). In the quasiclassical limit \(k_F \xi \gg 1\), the spectrum and the eigenfunctions may be easily found.\textsuperscript{9} The eigenvalues form a spectrum of equidistant levels
\[
E_\mu = \mu \omega_0,
\]
where the angular momentum \(\mu\) takes half-integer values, \(\mu = n + 1/2\), and
\[
\omega_0 = \frac{\int_0^\infty \Delta(r) dr}{\int_0^\infty e^{-2K(r)} dr},
\]
\[
K(r) = \int_0^r \frac{\Delta(r') dr'}{v_F}.
\]
where $H(t)$ is the Hamiltonian of the vortex at the position $\mathbf{r} = \mathbf{v} t$ with $\mathbf{v}$ the vortex velocity,

$$H(t) = \begin{pmatrix} H_0 + U(\mathbf{r}) & \Delta(\mathbf{r} - \mathbf{v} t) \\ \Delta^*(\mathbf{r} - \mathbf{v} t) & -H_0 - U(\mathbf{r}) \end{pmatrix},$$

(9)

and $U(\mathbf{r})$ is the potential set up by the impurities.

In the clean limit ($\Delta \tau \gg 1$), the admixture of bulk states (with energies greater than $\Delta$) to the vortex states may be neglected. We project the Hamiltonian (9) onto the subgap states of a clean vortex (7) by substituting

$$\Psi(\mathbf{r}, t) = \int_0^{2\pi} \frac{d\phi}{2\pi} a(\phi, t) \Psi(\phi, \mathbf{r} - \mathbf{v} t).$$

(10)

Defined in this way, the amplitude $a(\phi, t)$ has antiperiodic boundary conditions in $\phi$, $a(\phi + 2\pi) = -a(\phi)$. The time evolution of the coefficients $a(\phi, t)$ obeys the Schrödinger-type equation

$$i \frac{\partial a}{\partial t} = -i \omega_0 \frac{\partial}{\partial \phi} a + \frac{d\phi'}{2\pi} T_{\phi'} a(\phi')$$

$$+ \frac{d\phi'}{2\pi} L_{\phi'} a(\phi'),$$

(11)

where the kernel

$$T_{\phi'} = \langle \Psi(\phi, \mathbf{r} - \mathbf{v} t) | -i \frac{\partial}{\partial t} | \Psi(\phi', \mathbf{r} - \mathbf{v} t) \rangle = i \nu(\Psi(\phi) \nabla) \Psi(\phi')$$

(12)

is produced by the vortex motion, and the kernel

$$L_{\phi'} = \langle \Psi(\phi, \mathbf{r} - \mathbf{v} t) | U(\mathbf{r}) \nabla_z | \Psi(\phi', \mathbf{r} - \mathbf{v} t) \rangle$$

(13)

due to the impurities.

The $T$ kernel may be easily computed from the explicit form (7) of $\Psi(\phi)$. In the limit $k_F \xi \gg 1$, the matrix element (12) takes the form

$$T_{\phi'} = -2\pi \delta(\phi - \phi') \mathbf{k}_0 \mathbf{v}$$

(14)

and we identify this term with the “Doppler shift.”

The impurity potential $U(\mathbf{r})$ is taken as a sum over point-like impurities,

$$U(\mathbf{r}) = \sum_i V_i \delta(\mathbf{r} - \mathbf{r}_i).$$

(15)

Then the scattering kernel may be expressed as

$$L_{\phi\phi'} = 2i A^2 \sin \frac{\phi' - \phi}{2} \sum_i V_i e^{-2K(\mathbf{r}_i - \mathbf{v} t)\mathbf{v}} e^{i(k_0' - k_0)(\mathbf{r}_i - \mathbf{v} t)}.$$ 

(16)

Summarizing, we end up with the equation of motion (11) containing three terms: The first term describes the circular (“chiral”) motion of the quasiparticle in the vortex.\(^9,11,12\) The second term is the Doppler shift due to the vortex motion, and the third term describes the scattering off impurities (taking pointlike impurities is equivalent to including only $s$-wave scattering). We are interested in the energy pumping in this time-dependent model. Note that the physical energy is given by the first and third terms in the evolution operator (11), but does not include the second term ($T$ term) which arises from the time derivative of the basis wave functions. This discrepancy between the energy and the evolution operator may be resolved by an appropriate time-dependent gauge transformation

$$\tilde{a}(\phi) = a(\phi) e^{-ik_0' \mathbf{v} t}.$$ 

(17)

This gauge transformation has a dual effect on the equation of motion (11): First, it makes the energy operator coincide with the evolution operator. The old $T$ kernel is now replaced by a time-dependent one,

$$\tilde{T}_{\phi\phi'} = 2\pi \delta(\phi - \phi') \omega_0 (\mathbf{n} \times \mathbf{k}_0) \mathbf{v},$$

(18)

where $\mathbf{n}$ is the unit vector perpendicular to the plane (this gauge transformation resembles the one in electrodynamics replacing a static electric field with a magnetic field linearly growing in time). Second, the $L$ kernel is transformed as well and the new kernel takes the form

$$\tilde{L}_{\phi\phi'} = 2i A^2 \sin \frac{\phi' - \phi}{2} \sum_i V_i e^{-2K(\mathbf{r}_i - \mathbf{v} t)\mathbf{v}} e^{i(k_0' - k_0)(\mathbf{r}_i - \mathbf{v} t)},$$

(19)

which differs from Eq. (16) by the cancellation of the velocity term $\mathbf{v}$ in the last exponent.

The physical content of the two gauges may be understood in the following way: The basis wave functions (7) are quasiclassical plane waves (at the wave vector $k_F$) cut off by the long-wavelength envelope $\exp[-2K(r)]$ of the size of order $\xi$. In the original gauge [with variables $a(\phi, t)$], this basis was chosen by simply translating the basis (7) together with the vortex. In the new gauge [with variables $\tilde{a}(\phi, t)$], only the long-wavelength envelope is translated, without shifting the phases of the quasiclassical plane waves.

This difference in matching phases of plane waves at different vortex positions produces two different descriptions of the moving vortex. In the first gauge [variables $a(\phi, t)$], the evolution equation (11) contains impurities moving with respect to the vortex (fast oscillations in $L_{\phi\phi'}$). This description is similar to the approach taken in Refs. 10–12, a static vortex subject to moving impurities. However, in those references, the $T$ term was omitted. We will show below that omitting this term does not change the result for the dissipation in the moderately clean limit, thus justifying the approach of Refs. 10–12. In the second gauge [variables $\tilde{a}(\phi, t)$], there are no oscillating terms in $\tilde{L}_{\phi\phi'}$ except for the slowly varying envelope $K(r)$ whose time derivative may be neglected in most cases. All the oscillations in the $L$ term in the first gauge may be removed by a single gauge transformation, as all impurities move with respect to the vortex with the same velocity and in the same direction. This fact has not been properly taken into account in Ref. 12, which has led to an unphysical result. We shall comment in more detail on the derivation of Ref. 12 in Sec. V; here we just remark that the parallel motion of the impurities with
III. CIRCULAR-UNITARY ENSEMBLE OF THE QUASIPARTICLE LEVELS IN THE DISORDERED VORTEX

In this section, we review the derivation of the two-comb spectral statistics in the vortex from Refs. 11 and 12 and set up the notation for the calculations in the later sections. For the discussion of the spectral statistics in this section, we take the vortex at rest ($v=0$). Then the Hamiltonian in the equation of motion (11) contains only two terms, the kinetic term $-i\omega_0\partial_t\delta\phi$ and the scattering term $L_{\phi_d}\delta\phi'$ (for a vortex at rest there is no difference between $L_{\phi_d}$ and $L_{\phi_d}'$).

At not very high impurity concentration [see Eq. (38) below], the scattering kernel $L_{\phi_d}'$ may be approximated as a sum of two local terms [this approximation is due to the rapidly oscillating exponent in Eq. (16)],

$$L_{\phi_d'} = 4\pi i\omega_0 \sum_{i=1}^{N} [J_i \delta_{\phi_i,\phi_i'} - J_i^* \delta_{\phi_i,\phi_i'} + \phi_i - \phi_i']$$

where $N$ is the number of impurities in the core, the parameters $\phi_i$ specify the angular positions of the impurities, and $\delta_{\phi_i,\phi_i'}$ are $\delta$ functions smeared over the width $(\phi_i - \phi_i') \sim (\xi/k_F)^{-1/2}$ and antiperiodically continued in $\phi_i$ and $\phi_i'$. Note that the regularization (20) as a product of two smeared $\delta$ functions is important for evaluating the scattering matrix (24) below.\(^{11,12}\)

The effective strength of the $i$th impurity is

$$J_i = \frac{\pi^2 V_j e^{-2K(r_i)+2iK r_i}}{\omega_0 k F r_i} J_i^{-1} e^{-2K(r_i)+2iK r_i} = \frac{\pi^2 V_j}{\omega_0 k F r_i} J_i^{-1} e^{-2K(r_i)+2iK r_i},$$

where $\vartheta_i = mV_j$ is the Born parameter of the impurity (an additional imaginary unit compared to the notation in Ref. 12 is due to the antiperiodic boundary conditions employed).

The matrix elements (20) couple only angles with difference close to $\pi$. Introducing the two-component vector

$$\psi(\phi) = \begin{pmatrix} a(\phi) \\ a(\phi+\pi) \end{pmatrix}, \quad \phi \in [0; \pi],$$

the scattering becomes local in $\phi$. The individual scattering events in Eq. (11) then may be integrated separately and formulated in terms of a boundary condition\(^{12}\)

$$\psi(\phi_0 + 0) = M_i \psi(\phi_0 - 0),$$

where

$$M_i = \frac{1}{1 + |J_i|^2} \begin{pmatrix} 1 - |J_i|^2 & 2 J_i^* \\ -2 J_i & 1 - |J_i|^2 \end{pmatrix}.$$  

The scattering matrix $M_i$ is diagonal both in the limits of $J_i \ll 1$ and $J_i \gg 1$. The diagonal form of $M_i$ in the limit $J_i \gg 1$ is a consequence of the projection of the scattering prob-

The evolution of the wave function $\psi(\phi)$ is schematically shown in Fig. 1.

In the moderately clean limit with a sufficiently large (but not too large) number of impurities in the core, the matrix $M$ (and thus also $-i\sigma_y M$) is random with a uniform distribution over the SU(2) group. Such a random-matrix ensemble is classified as the “circular-ensemble” ensemble with dimension 2.\(^{20}\) The density of states and the level correlations may be easily computed from Eq. (27). For example, the average density of states is given by\(^{12}\)

$$\langle \rho(E) \rangle = \frac{2}{\omega_0} \sin^2 \left( \frac{\pi}{\omega_0} \frac{E}{\omega_0} \right).$$

The spectrum consists of two combs of equidistant levels: A level is characterized by the comb number $s = \pm 1$ and its position in the comb, $E_{\pm s} = E_0 \pm 2\omega_0 k$, where $E_0$ is the eigenvalue of the lowest level with positive energy ($0 \leq E_0 < \omega_0$). The eigenfunctions can be written explicitly as.
\[ \psi_{\pm,k}(\phi) = e^{i\phi} \delta_{\pm,k} M_{\phi,\phi} \psi_{\pm}(\phi = 0), \]

where \( \psi_{\pm}(\phi = 0) \) are the eigenvectors of \(-i \sigma_j M\), and the scattering matrices \( M_{\phi,\phi'} \) are defined as

\[ M_{\phi,\phi} = M_{i_n} \cdots M_{i_1}, \quad \phi > \phi_n > \cdots > \phi_1 > \phi', \]

where the product is taken over all impurities between the angles \( \phi' \) and \( \phi \). Equation (30) introduces \( M_{\phi,\phi'} \) for \( \phi > \phi' \); furthermore, it is convenient to define the scattering matrix for \( \phi < \phi' \) as \( M_{\phi,\phi} = M^\dagger_{\phi',\phi} \). The symmetry of the SU(2) matrices

\[ M^*_{\phi,\phi} = \sigma_y M_{\phi,\phi} \sigma_y \]

allows us to translate easily between the eigenvectors for the two series of levels via

\[ \psi_{\pm,-k}(\phi) = \sigma_y \psi^\dagger_{\pm,k}(\phi). \]

In our calculations, we shall need not only the properties of the spectrum, but also some statistical properties of the wave functions in the regime of the circular-unity ensemble. At any given point \( \phi \) and for any energy level, the wave function \( \psi(\phi) \) is a spinor pointing in a random direction. All directions are equally probable, allowing us to compute equal-point correlation functions such as

\[ \langle \psi(\phi) \sigma_{\alpha} \psi(\phi) \psi^\dagger(\phi) \sigma_{\beta} \psi(\phi) \rangle = \frac{\delta_{\alpha\beta}}{3}, \]

\[ \langle \psi(\phi) \sigma_{\alpha} \psi^\dagger(\phi) \psi^\dagger(\phi) \sigma_{\beta} \psi(\phi) \rangle = 2 \frac{\delta_{\alpha\beta}}{3}. \]

The correlations between wave functions at different values of \( \phi \) may be expressed in terms of the properties of the scattering matrices (30). The angular correlations between scattering matrices decay exponentially,

\[ \langle M_{\phi,\phi'} \sigma_z M_{\phi,\phi'} \rangle = e^{-|\phi - \phi'|/\phi_z}, \]

where

\[ \frac{1}{\omega_0 \tau} = \frac{1}{\dot{\phi}_z} = 16 n_{\text{imp}} \int_0^\infty r \, dr \int_0^\infty \frac{|J(r)|^2}{[1 + |J(r)|^2]^2}, \]

and \( n_{\text{imp}} \) is the impurity concentration. In Eq. (35), we have assumed (for simplicity) that all impurities have equal Born parameters, in which case the effective impurity strength \( J_i \) as given by Eq. (21) becomes a function of \( r_i \) and is denoted \( J(r) \) in Eq. (35). In order to derive Eqs. (34) and (35) one takes a small increment of \( (M_{\phi,\phi'} \sigma_z M_{\phi,\phi'}) \) in \( \phi \) and averages over a single impurity scattering matrix,

\[ \frac{\partial}{\partial \phi} \langle M_{\phi,\phi'} \sigma_z M_{\phi,\phi'} \rangle = 2 n_{\text{imp}} \int_0^\infty r \, dr \int_0^\infty \frac{|J(r)|^2}{(1 + |J(r)|^2)^2} \left( \langle M_{\phi,\phi'}^\dagger M_{\phi,\phi'} \sigma_z M_{\phi,\phi'} \rangle - \langle M_{\phi,\phi'}^\dagger \sigma_z M_{\phi,\phi'} \rangle \right). \]
[we assume that the Born parameter \(\delta<1\) and make use of Eq. (37); for \(\delta\sim1\) one should replace \(\ln 1/\delta\) by 1]. For stronger disorder (i.e., larger scattering rate \(1/\tau_h\)) or smaller Born parameter \(\delta\), the instant-scattering approximation (20) fails and the circular-unity ensemble crosses over to the class \(C\) ensemble. \(11,15\) A phenomenological approach to this crossover has been discussed in Ref. 22 and the results of numerical simulations are available in Ref. 23.

**IV. TWO REGIMES OF DISSIPATION**

The time evolution of the core states is described by Eq. (11). Since the evolution operator is nonstationary (i.e., explicitly time dependent), it causes transitions between levels with different energy. In a fermionic system, the rate of downward transitions is suppressed compared to the rate of upward transitions due to the Paule exclusion principle, leading to an increase of the average energy with time. The energy pumped into the system will finally be transferred to the thermal bath via the interaction with phonons or other soft degrees of freedom, thus producing a finite dissipation.

There are two different mechanisms of dissipation depending on whether the individual energy levels can be resolved or not. \(18\) If the discrete spectrum is smeared into a continuous one, the energy pumping can be calculated with the help of the standard linear-response Kubo formula. \(19\) This regime is naturally realized when the inelastic width \(\gamma_\text{in}\) of an energy level exceeds the mean level spacing \(\omega_0\). On the other hand, the spectrum may turn out effectively continuous even at \(\gamma_\text{in}<\omega_0\) if the time dependence of the evolution operator on the right-hand side of Eq. (11) is so fast that it destroys the instantaneous adiabatic spectrum. \(18\) In this case, the frequency \(\gamma_\text{e}\) of perturbations due to the nonadiabaticity of the spectrum exceeds \(\omega_0\) and plays the role of the effective level width. In the opposite case, when \(\gamma_\text{in},\gamma_\text{e}<\omega_0\), the spectrum is essentially discrete and the dissipation is due to rare Landau-Zener transitions \(17\) taking place when two levels come very close to each other.

In a normal metal at low temperatures, the inelastic widths due to the electron-electron and electron-phonon interactions are given by \(\gamma_\text{e-e} \sim T^2/E_F\) and \(\gamma_\text{e-ph} \sim T^3/\Theta_D^2\), respectively \(24\) (\(\Theta_D\) is the Debye temperature). Since \(\gamma_\text{e-e}\) is of the order of \(\omega_0\) already at \(T \sim \Delta\), it does not contribute to the level smearing at lower temperatures. Furthermore, for the states localized in the vortex core the interaction with phonons appears to be strongly suppressed compared to the normal-state rate; \(25\) one of the main reasons is that the quasiparticles with energy \(\mu \omega_0 \ll \Delta\) are composed of nearly equal mixtures of electron and hole components [i.e., \(\langle u^\dagger p u \rangle \approx \langle u^\dagger p \rangle\), cf. Eq. (6)] with negligible net charge. Thus, at sufficiently small temperatures \(T \ll \Delta\), the inelastic width of the core states \(\gamma_\text{in} \ll \omega_0\) and the regime of dissipation is determined solely by the vortex velocity. In Ref. 10, the crossover velocity \(v_K\) separating the regimes with discrete and continuous spectra was estimated as

\[
v_K \sim \frac{\Delta/p_F}{\sqrt{k_F l}}
\]

and we will present a microscopic derivation of this result below.

For model Hamiltonians from the three Wigner-Dyson random-matrix ensembles, dissipation was calculated by Wilkinson \(18,26\) in the regimes of small \((v \ll v_K)\) and large \((v \gg v_K)\) velocities (in the limit \(\gamma_\text{in}=0\)). He finds that if the Hamiltonian \(H(X)\) of the system depends on time through \(X=ut\), then the energy dissipation is determined by the variance of the level velocity \(C(0)=(\langle \partial E/\partial X \rangle^2)/\omega_0^2\) normalized by the mean level spacing \(\omega_0\). In the continuous-spectrum regime specified by \(v \gg v_K = \omega_0 C^{-1/2}(0)\), the energy dissipation rate as given by the Kubo formula \(18,27\)

\[
W_\text{Kubo} = \frac{\beta}{2} \pi C(0) v^2,
\]

describes viscous damping both for the orthogonal \((\beta=1)\), unitary \((\beta=2)\), and symplectic \((\beta=4)\) ensembles. In the discrete-spectrum regime, at \(v \ll v_K\), the result crucially depends on the level-repulsion parameter \(\beta\), which determines the probability \(P(e) \propto e^{\beta/2}\) to find two levels at a distance \(e \ll \omega_0\). In this situation, the energy dissipation rate is given by the expression \(18\)

\[
W_\beta \approx v^{(\beta + 2)/2},
\]

hence the dissipation is super-Ohmic for the Gaussian orthogonal ensemble, while for the Gaussian unitary ensemble it remains Ohmic with \(W_2 = \pi C(0) v^2\), exactly coinciding with \(W_\text{Kubo}\) despite a very different mechanism of dissipation.

In the following sections, we calculate the dissipation rate for the vortex motion in the regime of the Koulakov-Larkin two-comb spectrum, \(12\) both in the limits of small and large velocities, thus extending Wilkinson’s considerations to the case of circular-unity ensembles.

**V. DISSIPATION IN THE DISCRETE SPECTRUM (LANDAU-ZENER REGIME)**

In this section, we calculate the dissipation for the two-comb level structure described in Sec. III at small velocities. We will work in the “tilded” basis \(a(\phi,t)\) introduced in Eq. (17), where the energy coincides with the expectation value of the evolution operator (11), with \(T_\phi a\) and \(L_\phi a\) substituted by their tilded counterparts (18) and (19). In the low-velocity limit, the energy is pumped into the system when two levels come very close to each other and a nonadiabatic Landau-Zener (LZ) transition becomes possible. Due to the symmetry of the two-comb spectrum, the rate \(R_{LZ}\) of such transitions is the same for each neighboring pair of levels. We will calculate \(R_{LZ}\) by considering the lowest level with positive energy \(e\) and its mirror image with energy \(-e\). For simplicity, we assume that the vortex moves in the \(x\) direction, \(u_x=0\).

Following the logic of Ref. 18, we diagonalize the Hamiltonian at \(t=0\) and restrict it to the 2×2 matrix involving the pair of states considered,
\[ \check{H}(t) = \begin{pmatrix} e + h_{11}t & h_{12}t \\ \Bar{h}_{12}t & -e - h_{11}t \end{pmatrix}, \]  
where \( h_{ij} \) are the elements of the matrix \( \partial H/\partial t \) [neglecting the quadratic term \( (\partial^{2} H/\partial t^{2})^{2} \) is justified in the Landau-Zener regime, since the duration of a nonadiabatic transition is proportional to the gap of the avoided crossing and is small at \( \nu \ll \nu_{K} \)]. The instantaneous adiabatic spectrum takes the form

\[ E(t) = \pm \sqrt{\Delta_{LZ}^2 + \Delta_{F}^2 (t - t_{LZ})^2}, \]

where

\[ \Delta_{LZ}^2 = \frac{\epsilon^2 |h_{12}|^2}{A^2}, \quad A^2 = \bar{h}^2_{11} + |h_{12}|^2, \quad t_{LZ} = -\frac{\epsilon h_{11}}{A^2}. \]

Equation (43) describes an avoided crossing with the minimal distance (Landau-Zener gap) \( 2\Delta_{LZ} \) between the spectral branches realized at \( t = t_{LZ} \). The probability of the Landau-Zener transition at such a crossing is

\[ \exp(-\pi \Delta_{LZ}^2 / A). \]

The mean rate of transitions is given by

\[ R_{LZ} = \delta(t_{LZ}) \exp(-\pi \Delta_{LZ}^2 / A), \]

where the role of \( \delta(t_{LZ}) \) is to count each avoided crossing once. The average in Eq. (45) is taken over the distribution of the parameters \( \epsilon, h_{11}, \) and \( h_{12} \) describing the avoided crossing. The energy \( \epsilon \) is expressed through the transfer matrix \( M \) according to Eq. (27). The coefficients \( h_{11} \) and \( h_{12} \) are the matrix elements of the perturbation (18) over the exact wave functions \( \psi_{\pm}(\phi) = \psi_{\pm,0}(\phi) \) [which depend on the trajectory \( M_{\phi,0} \) via Eq. (29)],

\[ h_{11} = \omega_{0}k_{F}\sqrt{\frac{\pi}{\epsilon}} \left( 1 / \epsilon \right) \sigma_{z} \psi_{+}(\phi) \cos \phi, \]

\[ h_{12} = \omega_{0}k_{F} \sqrt{\frac{\pi}{\epsilon}} \left( 1 / \epsilon \right) \sigma_{z} \psi_{-}(\phi) \cos \phi. \]

We come to the crucial point: The quantities \( \epsilon, h_{11}, \) and \( h_{12} \) have different dependencies on the transfer matrix \( M_{\phi,0} \). In the moderately clean limit, when the number of impurities in the core is sufficiently large and \( \nu \ll 1 \), the matrix \( M_{\phi,0} \) performs many rotations over the SU(2) group. Therefore, we conclude that (i) \( \epsilon, h_{11}, \) and \( h_{12} \) are uncorrelated, and (ii) the distribution of \( h_{11} \) and \( h_{12} \) is Gaussian. We further calculate the variances of \( h_{11} \) and \( h_{12} \). For \( \langle h_{11}^2 \rangle \) we obtain with the help of Eq. (34),

\[ \langle h_{11}^2 \rangle = \left( \omega_{0}k_{F} \sqrt{\frac{\pi}{\epsilon}} \right)^2 \left( \frac{\pi}{\epsilon} \right)^2 \cos \phi \cos \phi' \epsilon^{-|\phi - \phi'|/\phi}, \]

\[ \times \langle \psi_{+}(\phi) \sigma_{z} \psi_{+}(\phi) \cdot \psi_{+}^{*}(\phi) \sigma_{z} \psi_{+}(\phi) \rangle. \]

Integrating over \( \phi - \phi' \) and averaging over the spinor \( \psi(\phi) \) according to Eq. (33a) we find

\[ \langle h_{11}^2 \rangle^{2} / (\omega_{0}k_{F} \sqrt{\frac{\pi}{\epsilon}})^2 = \frac{3}{\pi}, \]

Analogously, we obtain

\[ \langle |h_{12}|^2 \rangle / (\omega_{0}k_{F} \sqrt{\frac{\pi}{\epsilon}})^2 = \frac{2}{\pi}. \]

In the same way it can be shown that \( \langle h_{11} h_{12} \rangle = 0 \), thus proving the statistical independence of \( h_{11} \) and \( h_{12} \). We conclude that \( h_{11}, \) \( Re h_{12}, \) and \( Im h_{12} \) are independently distributed with the same distribution

\[ \mathcal{P}(h) = \frac{1}{2} \exp\left( -\frac{3 \pi h^2}{2 \phi_{r}^2 (\omega_{0}k_{F} \sqrt{\frac{\pi}{\epsilon}})^2} \right). \]

The distribution function for \( \epsilon \) is provided by the density of states (28), in the limit \( \nu \ll \nu_{0}, \mathcal{P}(\epsilon) = 2 \pi^{2} \epsilon^{2} / \nu_{0}^{3}. \)

Averaging Eq. (45) over \( \epsilon, h_{11}, \) and \( h_{12} \) with the distributions \( \mathcal{P}(\epsilon) \) and \( \mathcal{P}(h) \), we obtain for the mean rate of Landau-Zener transitions

\[ R_{LZ} = \frac{k_{F} \sqrt{\frac{\pi}{\epsilon}} \phi_{r}}{2 \omega_{0}}. \]

The energy dissipation rate is given by \( W = \omega_{0} R_{LZ} = \eta \nu^2 \) with the vortex viscosity

\[ \eta = \frac{1}{2} k_{F} \phi_{r} = \frac{1}{2} \omega_{0} \tau. \]

As defined by Eq. (53), \( \eta \) is a two-dimensional viscosity. In a layered superconductor, it determines the friction force \( F = -\eta \nu \) exerted on the vortex from excitation of quasiparticles within one layer.

The statistics (51) of the matrix elements of \( \partial H/\partial t \) determines the sensitivity of the spectrum to the vortex motion and allows one to find the critical velocity \( \nu_{K} \) separating the regimes of discrete and continuum spectra. The discrete spectrum can be resolved if the change of the Hamiltonian during the time \( \omega_{0}^{-1}, \delta H / \hbar \omega_{0} \), is smaller than \( \omega_{0} \). Taking for \( h \) the dispersion of the distribution (51), we find for the critical vortex velocity

\[ \nu_{K} = \frac{\omega_{0}}{k_{F} \sqrt{\phi_{r}}}, \]

coinciding with the estimate (39) found in Ref. 10.

Comparing with Ref. 12, we find that our result (53) for the viscosity is smaller by a factor \( \phi_{r} \) and the expression (54) for \( \nu_{K} \) is larger by the factor \( 1/\phi_{r} \). In Ref. 12, following the analysis in Refs. 10 and 11, it was assumed that the dissipation is produced by impurities moving with respect to the vortex, equivalent to neglecting the Doppler-shift term \( T_{\phi,\phi'} \) in Eq. (11). In order to identify the origin of the discrepancy in the results and verify the validity of omitting the Doppler shift, we reconsider below the treatment of Ref. 12—we will see that the source of the disagreement is not in the neglect of the Doppler-shift term but in the neglect of...
cross correlations between the motion of different impurities. To demonstrate this, we adopt the approach of Ref. 12 (omitting the Doppler-shift term) and recalculate the correlator of the spatial gradients of the matrix $M$, 

$$C = \frac{1}{4} \left( \frac{\partial M}{\partial x} \right)^2,$$  

(55)

from which the viscosity follows via $\eta = 2C/\pi$. Comparison between Eqs. (55) and (40) shows that the quantity $(2/\pi^2)C$ plays the role of the correlation function $C(0)$.

The matrix $M$ specified in Eq. (26) is a product of transfer matrices of individual impurities. Therefore, there are two contributions to the correlator (55), one originating from derivatives over the coordinates of the same impurity (diagonal part) and a second one from derivatives taken on different impurities (off-diagonal part),

$$C_{\text{diag}} = \frac{1}{4} \sum_i \left( \text{tr} \left( \frac{\partial M}{\partial x_i} \right) \right),$$  

(56)

$$C_{\text{off-diag}} = \frac{1}{4} \sum_{i \neq j} \left( \text{tr} \left( \frac{\partial M}{\partial x_i} \right) \text{tr} \left( \frac{\partial M}{\partial x_j} \right) \right).$$  

(57)

The diagonal part is given by $^{12}$

$$C_{\text{diag}} = \frac{\pi k_F^2}{4 \phi_\tau},$$  

(58)

The cross term, expressing the correlated nature of the motion of the impurities with respect to the vortex, has been missed in Ref. 12. Its calculation is presented in the Appendix and the result takes the form

$$C_{\text{off-diag}} = -\frac{\pi k_F^2}{4 \phi_\tau (1 + \phi_\tau^2)}.$$  

(59)

We thus see that the two contributions $C_{\text{diag}}$ and $C_{\text{off-diag}}$ nearly cancel each other and the net sensitivity of the spectrum to the vortex motion appears to be significantly lower than that found in Ref. 12,

$$C = \frac{\pi k_F^2 \phi_\tau}{4},$$  

(60)

where we employed the condition $\phi_\tau \ll 1$ of the moderately clean limit. Using Eq. (55), one recovers the result (53) for the vortex viscosity. The above consideration not only corrects the result of Ref. 12; in addition, it serves as a microscopic justification of the model adopted in Refs. 10–12, where the dissipation is due to impurities moving through the core and the Doppler-shift term $I$ in Eq. (11) is neglected.

VI. DISSIPATION IN THE CONTINUUM SPECTRUM (KUBO FORMULA)

If the vortex velocity $v$ exceeds $v_K$ the discrete spectrum is smeared and transitions between non-nearest levels become possible. In this limit, the energy dissipation can be calculated with the help of the Kubo formula; as in Sec. V we will use the tilded basis (17). Neglecting the slow time dependence of $\tilde{F}_{\phi \phi'}$, we write the evolution operator as $\tilde{H}(t) = H_0 + it$, where $H_0$ is the Hamiltonian of the vortex at rest and $I = \tilde{T}/t$ takes the form

$$I_{\phi \phi'} = 2\pi \delta(\phi - \phi')I(\phi),$$  

$$I(\phi) = \omega_\phi k_F v \cos \phi,$$  

(61)

where we again assumed that $v_J = 0$. The energy dissipation rate

$$W = \frac{dE}{dt} = \langle I \frac{\partial}{\partial t} \tilde{H}(t) | t \rangle$$  

(62)

is calculated as the linear response to the term $It$ with the help of the Kubo formula

$$W = i \int_{-\infty}^{0} t' dt' \langle 0 | [\tilde{I}(t'), \tilde{I}(0)] | 0 \rangle,$$  

(63)

where

$$\tilde{I}(t) = \int_{0}^{2\pi} I(\phi) \tilde{\Psi}^{\dagger}(\phi, t) \tilde{\Psi}(\phi, t) \frac{d\phi}{2\pi}$$  

(64)

and $\tilde{\Psi}(\phi, t)$ is a second-quantized operator in the interaction representation. The latter can be rewritten in terms of the (exact disorder dependent) eigenfunctions $\tilde{a}_n(\phi)$ and eigenvalues $E_n$ of the Hamiltonian $H_0$,

$$\tilde{\Psi}(\phi, t) = \sum_n \hat{c}_n \tilde{a}_n(\phi) e^{-iE_n t},$$  

(65)

with $\hat{c}_n$ the corresponding annihilation operators. Averaging over the initial state of the vortex at rest [so that $\tilde{a}_n(\phi)$ coincides with $a_n(\phi)$], one arrives at the expression

$$W = \int_{-\infty}^{0} t' dt' \int \frac{d\phi d\phi'}{(2\pi)^2} I(\phi) I(\phi') \times \sum_{km} (n_k - n_m) a_k(\phi) a^{\dagger}_k(\phi') a_m(\phi') a^{\dagger}_m(\phi) \times e^{i(E_k - E_m)(t' - t)},$$  

(66)

where $n_k = \langle \hat{c}_k^{\dagger} \hat{c}_k \rangle$ is the distribution function at the energy $E_k$. This expression can readily be represented (cf., e.g., Ref. 29) in terms of the Green functions

$$G_{E}^{R,A}(\phi, \phi') = \sum_n \frac{a_n(\phi) a^{\dagger}_n(\phi')}{E - E_n - i\delta},$$  

(67)
The above formula for the dissipation rate is not restricted to the regime of the circular-unitary ensemble, but is valid in the whole moderately clean limit regime as long as \( v \gg v_K \). In particular, one can easily recover the result of the standard quasiclassical analysis by assuming the \( \tau \) approximation: within this approach the Green function is diagonal in the momentum representation,

\[
\langle G_{E}^{k,A}(\mu) \rangle = \frac{1}{E - \omega_0 \mu + \frac{i}{2\tau}},
\]

and evaluating the integral in Eq. (68) one finds the energy dissipation rate \( W = \eta v^2 \) with the vortex viscosity coefficient

\[
\eta_\tau = \frac{1}{2} k_F^2 \omega_0 \tau.
\]

The \( \tau \) approximation is the simplest approach to the problem where all spectral correlations are neglected. Below, we will calculate the vortex viscosity for the case of the Koulakov-Larkin two-comb statistics and check how the presence of the two-comb correlations in the energy levels modifies the result (70). To this end we rewrite Eq. (68) in terms of the wave functions \( \psi_{is}(\phi) \) introduced in Eq. (29),

\[
W = -\frac{1}{2} \sum_{s,s',k,k'} \int \frac{d\phi d\phi'}{\pi^2} \int \frac{dE}{2\pi} \frac{\partial n(E)}{\partial E} \left( I(\phi)I(\phi') \right)
\times dt dt' e^{i\Phi} I(\phi) I(\phi')
\times \langle \psi_{s,k}(\phi) \sigma \psi_{s,k}(\phi) \psi_{s,k}(\phi') \sigma \psi_{s,k}(\phi') \rangle,
\]

where \( \Phi = E(t-t') - E_s t + E_s k t' \). We first reexpress the wave functions \( \psi_{is}(\phi) \) via Eq. (29) and perform the summation over \( k \) and \( k' \) according to the summation formula

\[
\sum_k e^{iE_k t} = \frac{\pi}{\omega_0} e^{-iE_0 t} \sum_{m=-\infty}^{\infty} \delta(t - \pi m/\omega_0)
\]

which produces a double infinite sum of \( \delta \) functions of \( t \) and \( t' \). We cut off the integrals over \( t \) and \( t' \) at some time scale smaller than \( \pi/\omega_0 \)—such a cutoff is equivalent to assuming a smearing of the energy levels with widths larger than \( \omega_0 \). Under this assumption, only one term of the double infinite sum survives with \( t = t' = (\phi - \phi')/\omega_0 \). Next, the integrations over \( t, t' \), and \( E \) can be trivially performed. Finally, we sum over \( s \) and \( s' \) and arrive at

\[
(\psi_{s,k}(0) M_{\phi,\phi'}^f \sigma_z M_{\phi,\phi'}(0) \psi_{s,k}(0) M_{\phi,\phi'}^f \sigma_z M_{\phi,\phi'}(0)) = tr(M_{\phi,\phi'}^f \sigma_z M_{\phi,\phi'} \sigma_z).
\]

This average is calculated with the help of Eq. (34) yielding

\[
\eta = \frac{k_F^2}{4 \pi} \int_0^\infty d\phi d\phi' \cos \phi \cos \phi' tr(M_{\phi,\phi'}^f \sigma_z M_{\phi,\phi'} \sigma_z)
\]

\[
= \frac{1}{2} k_F^2 \omega_0 \tau.
\]

The form of the above result coincides with Eq. (70) calculated within the \( \tau \) approximation. The microscopic expression for the elastic relaxation time \( \tau \) is given by Eq. (35). In case the inelastic relaxation time is shorter than \( \tau \), it substitutes the latter in Eq. (74).

To conclude this section we mention that the same result (74) can be obtained in the model where the Doppler-shift term \( T_{\phi,\phi'} \) in Eq. (11) is neglected and the dissipation is due to the motion of impurities with respect to the vortex. Within that model the energy dissipation rate is calculated as a linear response to a change in the impurity positions. The derivation formally repeats the one presented above but with the operator \( I_{\phi,\phi'} = v \partial L_{\phi,\phi'}/\partial x \). Performing the same manipulations leading to Eqs. (71) and (74) we obtain

\[
\eta = \frac{1}{4 \pi} \left( \frac{\partial M^f}{\partial x} \frac{\partial M}{\partial x} \right),
\]

where \( M \) is the product of scattering matrices defined in Eq. (26). The above correlation function for the random SU(2) matrix \( M \) can be related to the correlation function (55) and is equal to 8 C. Therefore, Eq. (75) exactly coincides with its low-velocity analog (55) and reproduces the result (74).

VII. DISCUSSION

The main conclusion of this paper is that the Bardeen-Stephen expression for the flux-flow conductivity is extremely insensitive to the details of the level correlations in the vortex core. We calculated the energy dissipation rate for the case of the Koulakov-Larkin two-comb level structure when the spectral correlations are most pronounced. Such a statistics, classified as the circular-unitary ensemble of dimension 2, is obtained for layered superconductors within the region of the moderately clean limit specified by Eq. (38). We found that the vortex viscosity is the same for the regimes of discrete \( (v < v_K) \) and continuum \( (v > v_K) \) spectra and coincides with the result (70) of the phenomenological \( \tau \) approximation. The viscosity \( \eta \) determines the flux-flow dissipative conductivity via the standard relation \( \sigma_{xx} = e c \eta / \pi B \). Assuming a cylindrical Fermi surface, we arrive at the result (1) obtained previously via several quasiclassical approaches. \(^{2-7}\)

Despite that we found the same result for \( \sigma_{xx} \) in the limits of small and large vortex velocities, it is worth emphasizing that the physics of energy dissipation is quite different in the
two limits. In the Kubo regime ($\nu > \nu_K$) the energy is pumped continuously, whereas in the Landau-Zener regime ($\nu < \nu_K$) it is absorbed in discrete portions of size $\omega_0$. The equivalence between the $\tau$ approximation and the result of the exact microscopic treatment is not very surprising in the Kubo regime, as in this limit it is determined by the net sensitivity of the spectrum to the vortex displacement rather than by interlevel correlations. On the other hand, in the Landau-Zener regime, this equivalence is a matter of coincidence: it relies on the fact that the vortex Hamiltonian belongs to the circular-unitary universality class characterized by a level-repulsion parameter $\beta = 2$.

The other outcome of the present work is that it provides a justification for neglecting the Doppler-shift $T$ term, Eq. (12), that was implicitly assumed in earlier papers. Without the $T$ term, the system is equivalent to a vortex at rest with impurities moving through its core. The dissipation is then related to the change of the level positions due to the motion of the impurities. On the other hand, the $T$ term describes the electric field in the core, which is the source of energy dissipation in the Bardeen-Stephen model—omitting this term is a bit confusing. Nevertheless, our analysis indicates that the vortex viscosities calculated with and without this term coincide in the moderately clean limit. One may expect, however, that a correct treatment of this term is crucial in the calculation of the Hall conductivity and in the superclean limit.

In this paper, we considered a strictly two-dimensional superconductor (or layered superconductor with negligible interlayer coupling). In the case of the Koulakov-Larkin circular-unitary-ensemble statistics, the effect of interlayer hopping is small provided that the effective quasiparticle temperature in the core, $T_{\text{core}}$, is smaller than $\omega_0(m_c/m_{ab})$, where $m_c/m_{ab}$ is the effective mass anisotropy. This condition ensures that the interlayer hopping amplitude is always smaller than $\omega_0$ and can be neglected. This behavior is to be contrasted with the one for the class $C$ random-matrix statistics realized in the moderately clean case for weak impurities ($\theta \ll 1$) and in the dirty ($\Delta \tau \approx 1$) limit. In that case, the interlayer coupling leads to tunneling from the $n$th level in one layer to the $m$th level in the adjacent layer, thereby opening an interlayer channel for energy dissipation. The competition between the intralayer and interlayer channels may lead to a strong deviation from the Bardeen-Stephen formula (1) and even to hysteretic behavior of the current-voltage curve. On the contrary, the two-comb spectrum is absolutely rigid: the $n$th level in one layer can have an avoided crossing only with the $n$th level in the adjacent layer and the tunneling between these two levels does not result in dissipation.

**ACKNOWLEDGMENTS**

We thank M. V. Feigelman and A. I. Larkin for many useful discussions. This research was supported by the SCOPES program of Switzerland, the Dutch Organization for Fundamental Research (NWO), the Russian Foundation for Basic Research under Grants Nos. 01-02-17759 and 02-02-06238, the program “Quantum Macrophysics” of the Russian Academy of Sciences, the Russian Ministry of Science, the Russian Science Support Foundation (M.A.S.), and the Swiss National Foundation. M.A.S. thanks ETH Zürich for hospitality.

**APPENDIX**

Here, we calculate the off-diagonal correlation function $C_{\text{off-diag}}$ defined in Eq. (57). To this end we divide the angle interval $[0, \pi]$ into many small pieces $[\phi^{(k-1)}, \phi^{(k)}]$ of width $\delta \phi \to 0$ so that each piece contains one impurity at maximum. The transfer matrix of the $k$th interval is then $M_{\phi^{(k)}, \phi^{(k-1)}} = 1$ (no impurities) or $M_{\phi^{(k)}, \phi^{(k-1)}} = M_i$ (if the angle of the $i$th impurity $\phi_i \in [\phi^{(k-1)}, \phi^{(k)}]$). Then

$$C_{\text{off-diag}} = \frac{1}{4} \sum_{k \neq p} \left( \text{tr} \left[ \frac{\partial M_{\phi^{(k)}, \phi^{(k-1)}}}{\partial x} \right] \times M_{\phi^{(k-1)}, \phi^{(p-1)}} \text{tr} \left[ \frac{\partial M_{\phi^{(p)}, \phi^{(p-1)}}}{\partial x} \right] M_{\phi^{(p-1)}, \phi^{(k)}} \right)$$

where $R = M_{\phi^{(k)}, \phi^{(p)}}$ and $Y(k) = \frac{\partial M_{\phi^{(k)}, \phi^{(k-1)}}}{\partial x} M_{\phi^{(k)}, \phi^{(k-1)}}$, $\tilde{Y}(p) = M_{\phi^{(p)}, \phi^{(p-1)}} \frac{\partial M_{\phi^{(p)}, \phi^{(p-1)}}}{\partial x}$.

The representation (A1) is suitable for averaging over disorder, since one can independently average the matrices $R$, $Y$, and $M_{\phi^{(p-1)}, \phi^{(p)}}$. The statistical independence of $Y(k)$, $\tilde{Y}(p)$, and $M_{\phi^{(p-1)}, \phi^{(p)}}$ follows from the fact that the intervals $[\phi^{(k-1)}, \phi^{(k)}]$, $[\phi^{(p)}, \phi^{(p-1)}]$, and $[\phi^{(p-1)}, \phi^{(p)}]$ do not overlap. As we will see below, the correlator (A1) is essentially nonzero at $[\phi^{(k-1)}, \phi^{(p)}]$; the matrix $R$, which couples $\phi^{(k)}$ and $\phi^{(k)}$ through the point $\phi = \pi$, is the product of a large number of matrices $M_i$ and loses all correlations within the interval $[\phi^{(p-1)}, \phi^{(p)}]$.

In calculating $\langle Y(k) \rangle$ and $\langle \tilde{Y}(p) \rangle$ with the help of Eqs. (24) and (21) only the fast phase of $J_s$ should be differentiated,

$$\langle Y(k) \rangle = - \langle \tilde{Y}(k) \rangle = i \sigma_2 k_F \cos \phi^{(k)} \delta \phi \int_0^\infty 2 \pi r \, dr \, \frac{4 |J(r)|^2}{[1 + |J(r)|^2]^2}$$

$$= i \sigma_2 k_F \cos \phi^{(k)}.$$

(A3)
with the last relation following from the definition (35) of the angle coherence length $\phi_r \ll 1$. Taking the continuum limit $\delta \phi \to 0$, we obtain

$$
C_{\text{off-diag}} = \frac{k_F^2}{4 \phi_r^2} \int d\phi_1 d\phi_2 \cos \phi_1 \cos \phi_2 \times \langle \text{tr} R \sigma_z \text{tr} R M_{\phi_2,\phi_1} \rangle.
$$

(A4)

Averaging over $M_{\phi_1,\phi_2}$ according to Eq. (34) and integrating over $(\phi_1 + \phi_2)/2$ we find

$$
C_{\text{off-diag}} = \frac{\pi k_F^2}{4 \phi_r^2} \langle \text{tr} R \sigma_z \text{tr} R \rangle \int_0^\infty d\phi e^{-\phi i \phi_1 \cos \phi},
$$

(A5)

where the upper limit is substituted by infinity due to the fast convergence of the integral. Finally, averaging over $R$ uniformly distributed over the SU(2) group and evaluating the remaining integral, we arrive at Eq. (59).

25. Wilkinson considered only the orthogonal and unitary ensembles, but the generalization to the symplectic ensemble is evident.
27. The integral in Eq. (21) of Ref. 12 should be normalized by the area $2\pi^2$ of the 4-sphere.
